Abstract

Background. The width of the buccal corridor (BC) is one of the factors affecting smile attractiveness.

Objectives. The aim of this study was to determine the effects of the BC size on the smile attractiveness of individuals with short, normal and long faces from the viewpoint of laypersons, general dentists and orthodontists.

Material and methods. Smiling photographs of male and female subjects who met the inclusion criteria were digitally altered to create 3 BC sizes (narrow: 2%; normal: 15%; wide: 28%) and 3 facial types defined by the facial index (FI) (short face: FI ≤ 83.9; normal face: 84.0 ≤ FI ≤ 87.9; long face: FI ≥ 88.0). Nine different combinations were made and the evaluators rated the overall attractiveness and acceptability of each smile on a 10-millimeter visual analog scale (VAS).

Results. A total of 53 raters (22 laypersons, 16 general dentists and 15 orthodontists) participated in this study. The orthodontists and general dentists had similar viewpoints and they preferred narrow and normal BCs over the wide ones in all facial types. Laypersons preferred normal BC for normal faces, while they did not distinguish different BCs in short faces.

Conclusions. Variations in the BC size affect smile attractiveness in different facial types and wide BCs are attributed to the least attractive smiles. Due to the different viewpoints of laypersons and professionals in this regard, there is no justification for expanding the maxillary arch to achieve more attractive smiles.

Key words: buccal corridor, smile attractiveness, facial type
Introduction

The increasing impact of facial attractiveness on self-perception and the way we are viewed by society cannot be overlooked.1–3 There are many different factors that constitute facial attractiveness.4–6 Among them, smile attractiveness is one of the most important. It affects our acceptability in social relationships by increasing self-confidence and results in communicating with a more confident feeling.7–9

In an attractive smile, a series of factors, including consonant curvature of the upper arch with the lower lip, proper alignment of the teeth with no crowding and no spacing, the width of buccal corridors (BCs), the amount of dental and gingival display, the color of the teeth and gingiva, absence of cant in the occlusal plane, and the number of teeth displayed during the smile are involved.10–14 On the other hand, the facial type (long face, short face or normal face) is another fundamental factor involved in determining smile attractiveness.15

Among the abovementioned factors, the BC width is the most challenging factor in smile attractiveness, as there is no consensus in the literature about its ideal size.9,16,17 This can be related to different etiologic factors affecting the size of BC, like maxillary deficiency in either transverse or sagittal dimensions,9,18–22 and extractions in the upper arch as a result of previous tooth loss or the orthodontic treatment plan.23 Most of the studies investigating the impact of BC on smile attractiveness used only close-up images of smiles.24–26 However, studies evaluating smile attractiveness should consider the facial type of the patient. The width of BCs in different facial types may seem different.17 At the same time, the perception of smile beauty and attractiveness may vary among different persons and among different societies. Smile attractiveness perception of a layperson may differ from that of professionals.27,28 Many articles have examined the effects of BC and the facial type on smile attractiveness,29–34 but no one has simultaneously evaluated the effect of these 2 factors from the viewpoints of laypersons, general dentists and orthodontists.

The present study is designed to assess smile attractiveness with regard to a different width of BC in different facial types from the viewpoint of general dentists, orthodontists and orthodontic patients as laypersons.

Material and methods

Ethical approval and consent

Ethical approval for this cross-sectional study was obtained from the Hamadan University of Medical Sciences Ethics Committee (Code: IR.UMSHA.REC.1395.36) and informed written consent was obtained from each patient whose photograph was used.

Image series construction

The frontal posed smile view of 2 subjects (1 male and 1 female) who met the inclusion criteria was chosen for this study. The inclusion criteria were as follows:
– complete incisors shown at smile (100%);
– coordination between the upper dental arch and the curvature of the lower lip during the smile (consonant smile arch);
– ideal anterior tooth alignment with no crowding and no spacing;
– medium BC size (15% of the distance between the right and left commissures)17,35,36;
– normal (mesoprosopic) facial type (facial index (FI) = 84.0–87.9%).34

The facial type of the subjects was determined using FI, which is the result of the division of the anterior face height (mm) by the bizygomatic width (mm). Anterior face height is the distance between the nasion soft tissue (Na) and the menton soft tissue (Men). The bizygomatic width of the face is the distance between the most prominent points on the zygomatic arches.

\[ FI = \left( \frac{Na - Men}{bizygomatic \ width} \right) \times 100, \]

where:
FI – facial index;
Na – nasion soft tissue;
Men – menton soft tissue.

After filling out the informed consent form, each patient’s frontal posed smile photograph was changed using Adobe Photoshop (CS5; Adobe Systems, San Jose, USA) to produce 2 types of independent variables:
– 3 different facial types according to the following standards: euryprosopic (short face): FI ≤ 83.9; mesoprosopic (normal face): 84.0 ≤ FI ≤ 87.9; and leptoprosopic (long face): FI ≥ 88.0;
– 3 different types of the BC size: narrow: 2% of the distance between the right and left commissures; normal: 15% of the distance between the right and left lip commissures; and wide: 28% of the distance between the right and left lip commissures.

Combining the 2 variables, 9 different posed smile photographs of each subject were obtained (Fig. 1,2). Then, the photographs were numbered in a randomized order, determined by the website www.randomizer.org, and these randomized sequences were given to each rater.

Raters

Three groups of raters were involved in this study:
– laypersons – orthodontic patients who had not started their orthodontic treatment yet (to avoid any impact of the expertise of orthodontists on their point of view);
— general dentists – general dentists who had not participated in orthodontic courses;
— orthodontists – orthodontists with clinical experience of at least 1 year.

The generated randomized sequences were shown to each evaluator; they were asked to rate the smile attractiveness of each picture by selecting a point along a visual analog scale (VAS), 10 cm (100 mm) in length. The VAS consisted of a bar labeled “Zero: the least attractive smile” on the left and “Ten: the most attractive one” on the right. The rate of smile attractiveness was reported as a value from 0 to 10. Smile attractiveness evaluations were done twice, with an interval of 4 weeks. In order to determine the reliability of the evaluations, 18 raters were selected randomly in such a way that each rater group included 6 samples.

Statistical analysis

Establishing a statistical power of 95% and a level of 0.05, the calculated sample size for each group of raters was 14 individuals. The data was analyzed by SPSS v. 17.0 software (IBM Corp., Armonk, USA). The repeated measures analysis of variance (ANOVA) was utilized for comparing differences between the groups. The least significant difference (LSD) test was used for all pairwise comparisons. The intraclass correlation coefficient (ICC) was used to find the correlation between the 1st and the 2nd VAS score.

Results

A total of 53 raters – 29 males (54.7%) and 24 females (45.3%) – participated in this study (22 laypersons, 16 general dentists and 15 orthodontists). The average age of the raters was 25.63 ±7.87 years for laypersons, 29.93 ±5.84 years for general dentists and 34.73 ±7.54 years for orthodontists (Table 1). The average period of clinical experience was 5.56 ±1.39 years and 5.86 ±1.39 years for general dentists and orthodontists, respectively.

VAS – visual analog scale; BC – buccal corridor.

Fig. 3. Smile attractiveness scores (VAS score) among different groups of BCs in different facial types
VAS – visual analog scale; BC – buccal corridor.
All 53 raters returned their completed papers. A good agreement between the 1st and the 2nd evaluation of smile attractiveness was observed (ICC = 0.884–0.952).

In the short facial type, repeated measurements ANOVA showed a significant difference among smile attractiveness of different BC groups rated by orthodontists (p < 0.001) and general dentists (p = 0.002) (Table 2). General dentists’ high score was 5.25 ±0.41 for the narrow BC type. They preferred narrow and normal BC types over the wide type (p = 0.001 and p = 0.005, respectively), but there was no difference between the narrow and normal ones (p = 0.698). Orthodontists’ high score was 4.93 ±0.41 for the narrow BC type. They preferred narrow over normal and wide BC types (p = 0.001 and p < 0.001, respectively), but there was no difference between the normal and wide types (p = 0.081). While laypersons’ scores showed no significant difference among different BC groups (p = 0.496), the narrow type reached the highest score (4.91 ±0.41) (Table 3, Fig. 3).

In the normal facial type, a significant difference in smile attractiveness was seen among different BC groups rated by laypersons (p = 0.003), general dentists (p < 0.001) and
orthodontists (p < 0.001) (Table 2). Laypersons’ high score was 6.80 ±0.31 for the normal BC type. They preferred the normal over the wide type (p < 0.001), but there was no difference between the narrow and normal types (p = 0.144) and between the narrow and wide ones (p = 0.066). General dentists, with a high score of 7.44 ±0.39 for the narrow BC type, preferred the narrow and normal over the wide type (p < 0.001 for both), but there was no difference between the narrow and normal ones (p = 0.161). Orthodontists’ high score (7.73 ±0.38) was assigned to the narrow BC type. They preferred the narrow and normal over the wide type (p < 0.001 for both), but there was no difference between the narrow and normal types (p = 0.062) (Table 3, Fig. 3).

With respect to the long facial type, a significant difference in smile attractiveness was seen among different BC groups rated by laypersons (p < 0.001), general dentists (p < 0.001) and orthodontists (p < 0.001) (Table 2). Laypersons, with a high score of 5.50 ±0.34 for the narrow BC type, preferred the narrow and normal over the wide BC type (p < 0.001 for both), but there was no difference between the narrow and normal types (p = 0.870). General dentists’ high score was 6.50 ±0.37 for the narrow BC type. They also preferred the narrow and normal types over the wide BC type (p < 0.001 for both), but there was no difference between the narrow and normal ones (p = 0.419). Orthodontists’ high scores (6.57 ±0.40 and 5.47 ±0.35) were assigned to the narrow and normal BC types, respectively. They preferred the narrow over the normal (p = 0.004) and wide types (p < 0.001). They also preferred the normal over the wide BC type (p = 0.001) (Table 3, Fig. 3).

Overall, regardless of facial types, a significant difference in smile attractiveness was seen among the different BC groups rated by laypersons (p < 0.001), general dentists (p < 0.001) and orthodontists (p < 0.001) (Table 2). Laypersons gave a high score of 5.57 ±0.20 to the normal BC type. They preferred the narrow and normal types over the wide one (p = 0.001 and p < 0.001, respectively), but there was no difference between the narrow and normal types (p = 0.805). General dentists’ high score was 6.40 ±0.24 and it was assigned to the normal BC type. They preferred the narrow and normal over the wide BC type (p < 0.001 for both), but there was no difference between the narrow and normal ones (p = 0.155). Orthodontists’ high score was 6.41 ±0.26 for the narrow BC type. They preferred the narrow over the normal and wide types, and also the normal over the wide BCs (p < 0.001 for all) (Table 3, Fig. 3).

Discussion

The present study investigated the impact of the BC size among different facial types on the attractiveness of the smile. Previous studies showed both of these factors were important in this regard. Furthermore, in the literature, different judgments of smile attractiveness by different raters have been shown. Some studies assessed in this regard 5 different sizes of BC (2%, 10%, 15%, 22%, and 28%) and some others used 6 sizes (0%, 5%, 10%, 15%, 20%, and 25%). In our study, we constructed only 3 sizes of BC (2%, 15% and 28%). These were matched to the narrow, medium and wide sizes of the other studies and they seemed to be simpler to differentiate, especially for laypersons. Furthermore, regarding the facial type, some of the studies assessed just 2 facial types (short face and long face) and some assessed 3 facial types. We constructed 3 facial types (short face, normal face and long face) according to FI in order to compare smile attractiveness in each facial type.

Finally, regarding raters, most of the studies compared 2 types of raters, usually orthodontists and laypersons. In our study, we used 3 groups of raters: orthodontists, general dentists and laypersons. This design could cover different judgments between laypersons and professionals, and also differences between the viewpoints of general dentists and orthodontists, who are both highly involved in dental treatment plans and consultations.

Our results showed a total agreement from the viewpoints of general dentists and orthodontists. Although it was not always statistically significant, these raters preferred narrow over normal, and normal over wide BC types in all facial types. On the other hand, laypersons preferred normal and narrow types over the wide one, with the highest score for the normal BC type. This difference between raters’ viewpoints could be fundamental for practitioners when deciding upon expansion/extraction treatments plans, especially in borderline cases. The results showed that, although it was not statistically significant, the normal BC size was more attractive than narrow one from the point of view of laypersons. On the other hand, professionals preferred expanded arches with narrow BCs over the normal ones. Furthermore, both laypersons and professionals believed that wide BCs were attributed to the least attractive smiles, and this was consistent with the results of previous studies. Therefore, it could be concluded that in normal BC size patients with any facial type, it is better to maintain or expand the upper arch. Treatment plans which increase the width of the BC are not preferable from the viewpoints of any of the raters.

As discussed above, wide BCs resulted in the least attractive smiles in all facial types and among all raters, with the exception of the short facial type in the opinion of laypersons. When laypersons judged smile attractiveness in the short facial type, the wide BC type had a score of 4.73 ±0.38, which was between the normal and narrow BCs scores (4.45 ±0.32 and 4.91 ±0.41, respectively). Statistical analysis showed that there was no significant difference between each of these scores. This unusual pattern could be related to such factors as total lower scores.
of short facial types than other facial types or the small sample size of raters. On the other hand, when all facial types are combined together, a predictable pattern is observed in the laypersons’ opinions. They also marked the wide BC type as the least attractive one.

In the present study, all raters could distinguish the impact of different BCs on smile attractiveness in normal and long facial types, but laypersons could not differentiate between different BCs in short faces (Table 2). These findings are consistent with the results obtained by Zange et al. as to the long facial type part; orthodontists in both studies preferred the narrow BC for long face patients and they could differentiate between each pair of BC sizes. Laypersons were unable to differentiate the attractiveness of smiles except for the wide BC type. Conversely, in regard to the short facial type, our study is in contrast to the study by Zange et al. While we observed that laypersons could not find the differences between each BC, Zange et al. reported that laypersons differentiated each of the BC sizes included in our study (2%, 15% and 28%). Comparing the methodology, they constructed a video of photographs in which raters had only 15 s to evaluate each image and could not go back to see the previous image. They also were not able to compare the images at the same time. In our study, we showed all 9 images of both patients at the same time, with no restriction on the time of evaluation.

Our study investigated the impact of the BC size among different facial types from different viewpoints. It is suggested for future investigators to consider the effect of the patients’ sex and also to analyze the viewpoints of different raters, regarding not only their profession, but also their gender, in order to clarify whether the sex of the patients and/or of the raters has any effect on the results.

Conclusions

For all facial types, orthodontists and general dentists similarly stated that the narrower the BCs are, the more attractive the smile is. Wide (28%) BCs were attributed to the least attractive smiles in all facial types. In normal faces, laypersons, in contrast to the professionals, preferred the normal (15%) BC size. They also could not differentiate the effects of different BCs on the smile attractiveness of the short facial type.
