Dental treatment of post-myocardial infarction patients: A review of the literature

Abstract
Patients who have suffered a heart attack often require dental treatment. Inflammation of the oral cavity not only reduces the quality of life but also negatively affects the course of ischemic heart disease. Dental treatment in patients with a history of myocardial infarction seems complicated, since these patients require special consideration with regard to the timing and form of dental treatment, as well as the precautions required. Patients at risk of cardiac complications that are greater than the benefits of dental treatment should be identified, and only the most urgent conditions should be treated. The aim of this study is to present the latest guidelines for dental treatment in patients who have suffered myocardial infarction.

Key words: dental care, oral anticoagulants, antibiotic prophylaxis, myocardial infarction
Introduction

The number of patients with general conditions requiring dental treatment is on the increase. According to the estimates presented in Bhadteja’s report, out of 36,729 patients of Dental College and Hospital in Mathura, India, 58% had a history of cardiovascular disease. These patients require an individualized treatment plan and continuous monitoring of oral health. The current state of knowledge indicates that inflammation in the oral cavity, particularly periodontitis, affects the general state of health, including the development and course of atherosclerosis. Cardiovascular disease has an inflammatory origin. Firstly, there is an increase in the level of pro-inflammatory mediators in response to the presence of Gram-negative lipopolysaccharides, C-reactive protein (CRP), interleukin-1β and -6 (IL-1β and IL-6), tumor necrosis factor α (TNF-α), fibrinogen, and metalloproteinase 9 (MMP-9). These substances contribute to the destabilization of atherosclerotic plaque. Secondly, there is a cross-reaction of the patient’s antibodies with heat shock (HS) protein present in the damaged vascular endothelium and atherosclerotic plaques. This leads to a continuation of the inflammatory process and thus to the progression of the disease. Cross-reactivity is triggered by the presence of the oral bacteria Porphyromonas gingivalis and Tannerella forsythia, whose HS protein is 60% homologous with the HS protein found in mammals. Thirdly, direct bacterial mechanisms (e.g., bacterial enzyme activity) contribute to the progression of cardiovascular disease. Bacterial DNA of Tannerella forsythia, Porphyromonas gingivalis, Aggregatibacter actinomycetemcomitans, and Prevotella intermedia has been found in atherosclerotic plaque. Finally, the concept of “vascular endothelial activation” can explain the mechanism underlying inflammatory-induced atherosclerotic plaque formation. Lipopolysaccharide (LPS) binding, bacterial outer membrane vesicles, fimbriae, and other bacterial antigenic structures have an impact on the local and systemic host response. This leads to upregulation of endothelial cell receptors followed by monocyte vascular wall adhesion. Monocytes migrate into the subendothelial space, absorb low-density-lipoprotein (LDL) cholesterol and become foam cells. After their apoptosis, lipids are accumulated in the vessel wall, covered by matrix and accompanied by smooth muscle cell proliferation, which is induced by invasive periodontal pathogens. Enzymatic degradation of the extracellular matrix results in plaque rupture, exposure of prothrombotic components and subsequent thrombus formation, which ultimately leads to blood vessel occlusion. This results in a need for treatment of diseases of the oral cavity, as well as intensive efforts toward periodontal disease prevention in patients with cardiovascular diseases.

The need for periodontal treatment is significant among Polish patients following myocardial infarction. On the Community Periodontal Index of Treatment Needs (CPITN), 38.6% of them have a score of 3 and 46% a score of 4, meaning they are in urgent need of periodontal treatment. Questions concerning the safety of dental treatment of patients following myocardial infarction need to be addressed.

Material and methods

To identify key words, a Population, Intervention, Comparison and Outcome (PICO) question was formulated as: What are the safety rules for dental care of patients following myocardial infarction? A comprehensive search of the MEDLINE (PubMed), Scopus and Google Scholar electronic databases was undertaken in January 2019 to find relevant articles, using following search terms: [dental care OR dental anesthesia OR tooth extraction] AND [myocardial infarction OR ischemic heart disease]. The timeframe was 2000–2019. Additionally, a manual search of bibliographies of full-text articles was also conducted. The guidelines of the American Heart Association (AHA), American College of Cardiology, European Society of Cardiology (ESC) and Polish Society of Cardiology were also reviewed. We considered reviews, systematic reviews, guidelines, and statements of dental and cardiological associations, randomized controlled trials (RCTs), and cohort, case and cross-sectional studies. Papers with abstracts written in English or Polish were included. Letters, book chapters, case reports, studies without an abstract or where the full text was not available were not included. Only publications addressing the protocol for the treatment of post-myocardial infarction patients were analyzed. Articles dealing with the influence of oral inflammation on cardiovascular disease or the effects of dental treatment on general health were excluded.

Limitations of this review include the open PICO question, the broad spectrum of relevant issues requiring urgent explanation, and the restriction to cardiological society guidelines and reviews rather than RCTs. Taking all this into account, only some of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) rules could be fulfilled. The study selection was conducted independently by 2 reviewers (PL and RSZ), with any disagreements resolved by the 3rd reviewer (ED). A total of 37 articles were included in the review. No meta-analyses or systematic reviews were found.

Our findings were compatible with those presented by Napeñas et al. at a panel of experts at the 6th World Workshop on Oral Medicine. They stated that “[w]ith a lack of consensus statements, guidelines, or systematic reviews focused on these specific issues related to dental treatment for patients with cardiovascular diseases, the vast majority of current recommendations are not linked to levels of evidence and are presumably derived from expert opinion.”
Appropriate time to start dental treatment in post-myocardial infarction patients

Dental procedures are classified as minor surgical procedures of low cardiovascular risk. The risk of death or myocardial infarction within 30 days of a dental procedure is less than 1%. However, a patient following a heart attack is at high risk of the re-occurrence of cardiovascular events. Only considering patients with acute ST-elevation myocardial infarction (STEMI), the risk of in-hospital death ranges from 4% to 14% and the annual mortality after surgical intervention is 10%. Over 70% of relapses occur in the first month after the initial incident. The risk of recurrence depends on the severity of the disease, type of disease, the treatment applied, and possible complications of the infarction.

The most burdened group of patients are those treated conservatively – currently only a small number, due to the pressure of cardiac society guidelines pertaining to early invasive treatment. In these cases, the natural course of the disease lasts for more than 6 weeks. This is the period needed for a post-infarction scar to form, to create collateral circulation and to restore the contractility of damaged (but not necrotic) areas of the myocardium. To avoid late infarction complications, all procedures excluding emergency treatments should be avoided in this period. This also applies to dental surgery. Former AHA guidelines extended this period to 6 months, during which avoiding dental surgery was recommended, as the risk of complications was considered highest in this period.

Due to advances in cardiac management in the last 2 decades, these limitations are no longer recommended. Firstly, there is widespread access to invasive methods of treatment of infarctions, allowing immediate reperfusion of tissues, thus avoiding early and late complications. In addition, on the 2nd day after myocardial infarction patients are subjected to early cardiac rehabilitation; this is continued after discharge in rehabilitation centers, where patients undergo fitness tests in the first month of convalescence. When a patient’s test tolerance is found to be good, the risk of recurrence is considered low, and if the attending physician does not find otherwise, there are no contraindications to dental treatment. Patients who have had myocardial infarction in the past and are in a stable period of coronary heart disease do not need stress tests and can be assessed on the basis of an interview. In terms of metabolic equivalents of task (METs), efficiency at 4 METs is sufficient to qualify a patient for dental procedures.

Patients with the risk of cardiac complications exceeding the benefits of dental treatment should be identified and only the most urgent conditions should be treated. However, pain and inflammation, which may be a consequence of avoiding dental treatment as a precaution against cardiac complications, are a source of endogenous catecholamines that burden the already damaged heart muscle, which means caution might not always be the safest solution. The priority is to cure inflammation in the oral cavity, as it can cause pain similar to angina pectoris, with the same characteristic pain radiation. In addition, painful inflammation hinders food intake and interrupts sleep, resulting in a significant reduction in the quality of life. Endodontic treatment, conservative treatment, non-surgical periodontal treatment, or prophylactic treatment are considered procedures entailing a low risk of complications. In addition, the risk decreases in stable periods of coronary heart disease or after heart failure, when the symptoms have a constant intensity, are predictable and occur only after intense physical activity. A good determinant of a patient’s condition is a lack of chest pain for 2 weeks and satisfactory test results. Most authors recommend a cautious 4–6-week period post-myocardial infarction to stabilize the disease. During this period, the most indispensable procedures, such as extractions, drainage of abscesses or pulpotomies can be performed in a hospital setting. After this period, unless the cardiologist recommends otherwise, complex dental treatment can be carried out.

Antibiotic prophylaxis in post-myocardial infarction patients

Another issue is antibiotic prophylaxis prior to treatment associated with the risk of bacteremia in patients who have suffered myocardial infarction. Patients with angina pectoris, cardiovascular events or coronary artery bypass surgery (bypass grafts) are classified as patients with a low risk of infective endocarditis and therefore antibiotic prophylaxis is not indicated. The same applies to stent-injected patients. Guidelines set by the Polish Dental Association and National Antibiotic Protection Program in 2019 continue to support the 2015 guidelines of the European Society of Cardiology on the prevention and treatment of infective endocarditis (Table 1). They recommend the use of antibiotics in a number of situations, including the presence of an artificial prosthetic valve, the presence of artificial material used to repair the valve (e.g., a mitral ring) and cyanotic congenital heart disease. In cases of congenital heart defects repaired with artificial material, prophylaxis is recommended for 6 months after surgery, or permanently if the defect has not been completely corrected and there is intracardiac leakage. The guidelines do not include a history of myocardial infarction or bypass surgery as posing an increased risk of infection. They limit high-risk dental procedures to those in which the continuity of the mucous membranes is disrupted and the risk of injury to the gingival or periapical area is present. Such procedures require antibiotic prophylaxis only in selected cases mentioned above. However, some authors recommend antibiotics in the case of invasive procedures up to 30 days after cardiological intervention.
In each case, the benefits and risks of possible antibiotic usage should be balanced. It should be noted that in post-myocardial infarction patients there may be indications for antibiotic prophylaxis resulting from other concomitant diseases. The most important factors in the prevention of infective endocarditis are good oral hygiene and oral inflammation prophylaxis.

**Rules for safe dental treatment**

The basics of safe dental treatment of patients with cardiovascular diseases start with a detailed medical history including complaints, allergies, medications, and specialist recommendations. It is important to monitor the patient’s condition and to interrupt procedures when the patient becomes restless or cardiac problems arise. An angina attack can occur in the dental chair due to stress, pain and anxiety triggers. Pain can be felt in the jaw, from where it can radiate to the neck and throat, so in some cases the patient and the dentist may interpret it as toothache. If the patient experiences retrosternal pain, the procedure should be interrupted and sublingual nitroglycerin (0.4–0.8 mg) and oxygen (3L/min) should be administered. If the pain subsides within 5 min, the appointment can be continued or postponed to the next day. If the pain persists after 5 min, nitrates should be given again. If there is no improvement after 15 min from the first symptoms, a re-infraction should be suspected, and in this situation the patient should be transferred as soon as possible to an emergency department.

Psychological and physiological stress during dental appointments has the potential to significantly alter hemodynamic stability. This means a stress-reduction protocol is suggested for post-myocardial infarction patients, including profound local anesthesia, preoperative or intraoperative sedation and excellent post-operative analgesia. The dental visit should be short – up to 30 min – and in the middle of the day. Morning hours, with the highest incidence of myocardial infarction, and late afternoon hours, when fatigue and stress levels are high, should be avoided.

During dental procedures, a supine position should be avoided, as it leads to the return of blood from peripheral areas to the central circulation system and may overload pulmonary circulation. In cases of systolic heart failure following myocardial infarction, this overload may result in the aggravation of heart failure, including pulmonary edema after re-verticalization, and further contribute to orthostatic syncope. The patient should continue to take the medication before the appointment as directed by the attending physician. If the patient’s regular therapy includes nitrates, the patient should bring them. In cases of anxiety disorders and stress, administration of 5–10 mg of diazepam is recommended the night prior to the visit and 1–2 h before the treatment. In this case, the patient should not drive a motor vehicle.

**Local anesthesia in post-myocardial infarction patients**

Another important aspect of dental treatment is local anesthesia. If the patient’s condition is stable and medication is taken as prescribed, there are no contraindications for local anesthesia with adrenaline. Patients with ischemic heart disease are more vulnerable to the negative effects of the release of endogenous adrenaline as a result of severe pain during surgery than they are to a small amount of adrenaline in an anesthetic. A visit to a dental office is a stressful event, meaning the level of endogenous catecholamines increases more than after the administration of anesthesia. The level of endogenous adrenaline is naturally highest between 8 and 11 AM, so the visits should not be in the morning. Vanderheyden et al. showed that the highest increase in the level of adrenaline is associated with the beginning of the visit and the treatment itself. However, during...
the administration of anesthesia and immediately after an injection, increases in adrenaline levels were not observed.23 This means that most of the adrenaline is of endogenous origin, hence the reduction of stress and good, effective anesthesia are indicated. Moreover, local anesthetics without vasoconstrictors do not provide satisfactory hemostasis or anesthesia during dental procedures.25 However, it is recommended not to exceed 0.04 mg of adrenaline, which corresponds to 2 1.8-cc cartridges of anesthetic with adrenaline at a dilution of 1:100,000.14 If it is necessary to administer more anesthesia, subsequent portions should be administered without a vasoconstrictor. Intravascular anesthesia should be avoided.4 The use of intrapulpal and intraosseous anesthesia is contraindicated, as this could lead to excessive absorption of adrenaline.9 For this reason, retraction cords impregnated with adrenaline should be avoided. However, in the case of untreated, unregulated arrhythmias or unstable angina, vasoconstrictor substances are contraindicated. Similarly, caution with the use of vasoconstrictors is indicated in patients with pacemakers, especially implantable automatic defibrillators.23 Elad et al. showed that local anesthesia using articaine hydrochloride 4% with adrenaline 1:200,000 is as safe as local anesthesia with lidocaine and adrenalin 1:100,000.8

Hemostasis in post-myocardial infarction patients

Today the risk of complications of dental procedures is dependent more on the anticoagulant therapy used than on the severity of coronary heart disease. Patients who have had acute myocardial infarction always take medications that affect hemostasis.27 Depending on the indications, these are either antiplatelet drugs, vitamin K antagonists or new non-vitamin K antagonists (NOACs). Discontinuation of therapy with these drugs is associated with a high risk of complications, including death. This risk far exceeds the risk of increased bleeding during and after surgery. In addition, a surgical intervention itself increases the risk of deep vein thrombosis. Double antiplatelet therapy (DAPT) is aimed at preventing thrombosis in the coronary artery. The risk of thrombosis lasts until the atherosclerotic plaque stabilizes (a process lasting about 4–6 weeks) or – in the case of stent implantation – until it is covered with vascular endothelium (the conventional limit for metal stents is 1 month, and for coated stents 6–12 months). Double antiplatelet therapy includes acetylsalicylic acid and an inhibitor of the P2Y12 glycoprotein receptor (clopidogrel, prasugrel or ticagrelor).28 In cases when there is also a risk of cardiac embolism (atrial fibrillation, intracardiac thrombus) or a concomitant venous thromboembolism, DAPT treatment is supplemented with an oral anticoagulant.29

Today the risk of complications of dental procedures is dependent more on the anticoagulant therapy used than on the severity of coronary heart disease. Patients who have had acute myocardial infarction always take medications that affect hemostasis.27 Depending on the indications, these are either antiplatelet drugs, vitamin K antagonists or new non-vitamin K antagonists (NOACs). Discontinuation of therapy with these drugs is associated with a high risk of complications, including death. This risk far exceeds the risk of increased bleeding during and after surgery. In addition, a surgical intervention itself increases the risk of deep vein thrombosis. Double antiplatelet therapy (DAPT) is aimed at preventing thrombosis in the coronary artery. The risk of thrombosis lasts until the atherosclerotic plaque stabilizes (a process lasting about 4–6 weeks) or – in the case of stent implantation – until it is covered with vascular endothelium (the conventional limit for metal stents is 1 month, and for coated stents 6–12 months). Double antiplatelet therapy includes acetylsalicylic acid and an inhibitor of the P2Y12 glycoprotein receptor (clopidogrel, prasugrel or ticagrelor).28 In cases when there is also a risk of cardiac embolism (atrial fibrillation, intracardiac thrombus) or a concomitant venous thromboembolism, DAPT treatment is supplemented with an oral anticoagulant.29
Coronary angiography is routinely performed in patients with acute coronary syndrome, and if the coronary artery responsible for myocardial infarction is identified, a revascularization procedure is performed. Coronary angioplasty is the most common, with the implantation of an anti-proliferative eluting stent, coated with a cytostatic agent that inhibits cell division. This limits the inflammatory process and the formation of restenosis in the vessel, but at the same time slows down the epithelialization of the stent and prolongs the need for DAPT. New drug-eluting stents require the use of 2 antiplatelet drugs for around 6 months, or 12 months if they are implanted due to acute coronary syndrome. This is a conventional time period to allow the vascular endothelium to grow. Earlier discontinuation of therapy may result in acute thrombosis in the stent, myocardial infarction and death. In exceptional situations, metal stents are used; their epithelialization takes 1 month.29

Time limits for DAPT were modified by ESC guidelines published in 2017.29 Two scales were created to establish asafedate for ending this treatment. The Precise-DAPT score is used for stent implantation, based on the results of laboratory tests (hemoglobin, leucocytes, creatinine clearance) and patient data (age, a history of bleeding), and indicates either a brief (3–6 months) or extended (12–24 months) use of DAPT. Longer therapy may be beneficial and lead to a lower risk of the stent closing. However, the duration of therapy depends on individual factors (e.g., age, comorbidities, left ventricle ejection fraction, bleeding risk or smoking) as well as the procedure technique (implanted stent caliber, the type of substance released, the presence of a stent in the vein bridge).29,30

In 2016 Pruszczyk et al. published (in Polish) a paper detailing a protocol for preparing patients on anticoagulants for dental surgical procedures. It follows the guidelines set out by the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS).29 Most dental procedures are defined as low-risk in terms of blood loss, and hemostasis can be achieved through the use of local hemostatic agents. There is a greater risk of blood loss associated with major reconstructive procedures, bone block transplants, implantological procedures, extractions of more than 3 teeth, treatments with the elevation of the mucoperiosteal flap, soft tissue augmentation procedures, connective tissue grafts, and open sinus lift procedures. The 4 criteria for abundant post-operative bleeding are: bleeding lasting longer than 12 h, forcing the patient to report to the dentist’s office or the emergency room, hematoma or bruising, and the need for a blood transfusion.31

The effect of antiplatelet therapy may double the bleeding time, but in most cases it remains within the normal range or only slightly over it.31 The results of a platelet aggregation test might be abnormal, although without clinical consequences.32 Prolonged bleeding time is not a major clinical problem, since hemostasis can be achieved by pressure, suturing, applying collagen sponges, or prescribing tranexamic acid. As mentioned above, discontinuation of antiplatelet therapy is the main cause of late stent thrombosis, which can result in serious complications, including death (in up to 45% of cases) and significant damage to the heart.33 The safety of surgical dental procedures during antiplatelet therapy was confirmed by Park et al.34 Among 100 patients undergoing combined antiplatelet therapy with acetylsalicylic acid, clopidogrel and in some cases with the addition of cilostazol, only 2 patients had increased post-operative bleeding after tooth extraction, and in both, pressure was enough to stop the bleeding.32 Dodson demonstrated that the amount of bleeding measured during invasive procedures was similar in a group of patients who suspended their acetylsalicylic acid (ASA) therapy for 7 days before tooth extraction and in patients who continued their ASA therapy.33 However, Buhatem Meideiros et al. showed that patients on double antiplatelet therapy presented a larger volume of bleeding during invasive procedures than patients not using these medications.35 Local hemostatic methods were sufficient to control the bleeding and there were no post-operative bleeding complications in any of the presented cases.35 When in doubt, it is recommended to check prothrombin time (PT), partial thromboplastin time (PTT) and the number of platelets. If PT and PTT are found to be within the normal range and the number of plates exceeds 100,000/mm³, surgery can safely be performed.32 In more complicated surgical procedures with a moderate bleeding risk, patients should be maintained on aspirin, while P2Y12 inhibitor therapy should be discontinued.31

The vitamin K antagonists warfarin and acenocoumarol are used in conditions associated with coronary heart disease, including prophylaxis of venous thromboembolism, and in patients with arrhythmias, artificial valves, thrombophilia, and antiphospholipid syndrome.36,37 In these cases, administration of vitamin K antagonists should not be stopped before any dental procedures – including procedures with a higher risk of bleeding – if the patient’s INR < 3 24 h before the planned procedure.35 If the patient’s INR > 3, the attending physician should adjust the therapy to achieve a lower INR.31 Withdrawal of oral anticoagulants does not guarantee that bleeding will not occur; serious bleeding also occurs in patients who have never taken anticoagulants. Only 0–3.5% of cases of excessive bleeding are severe enough that they cannot be controlled with local measures. A higher risk (of death or permanent disability) is associated with discontinuation of anticoagulant treatment. In a relapse of venous thromboembolism, the risk of death is 6% and of permanent disability is 2%. In the case of arterial embolism, the former risk is 20% and the latter 40%.38 It should be emphasized that there is no description in the literature of any case of death or permanent disability resulting from massive bleeding after a dental procedure in a patient who was taking anticoagulants. It should be borne in mind that
during anticoagulant therapy, the administration of tetracyclines, erythromycin, clarithromycin, and metronidazole is contraindicated. 9

Newer anticoagulants are direct inhibitors of factor Xa – rivaroxaban, apixaban, edoxaban – and the direct thrombin inhibitor dabigatran. They are used in deep vein thrombosis, pulmonary embolism, embolism due to non-valvular atrial fibrillation, following orthopedic surgery, as well as in acute coronary syndrome and venous thromboembolism. There are no unambiguous guidelines of how to proceed with the use of these drugs in planned surgical procedures. The manufacturers of these drugs recommend a break of 1 day in pharmacotherapy, extended to 2 days in cases of impaired renal function with glomerular filtration rate (GFR) lowering to 30 mL/min/1.73 m². It is recommended that the procedure should be performed when the drug concentration is the lowest – that is, 12 h or 24 h after the last dose, depending on whether the drugs are taken once or twice daily. If procedures with a high risk of bleeding are planned and the medications are taken in the morning, the dose of the drug used once a day (edoxaban) should be delayed until after the procedure; with drugs taken twice daily (apixaban, dabigatran and rivaroxaban), the evening dose should be skipped. If edoxaban is taken in the evening, there is no need to skip the dose. If complete hemostasis is obtained during the procedure, the dose that was previously skipped can be taken after 6–8 h. 38 In patients taking medications affecting hemostasis, it is recommended that dental procedures should be performed early enough during the day to allow the patient to seek help in case of prolonged bleeding. Likewise, treatment should be carried out at the beginning of the week, as re-bleeding usually takes place after 24–48 h. 39 The use of an infiltration anesthetic should be avoided if possible. If nerve block anesthesia is necessary, it should always be performed with aspiration.

Following an extraction, the tooth socket should be provided with a hemostatic dressing and sutured well for 7–14 days, and gauze pad compression should be maintained for 30 min after treatment. 37 The patient should be advised not to rinse their mouth for 24 h, not to perform suction or create negative pressure in the mouth, not to touch the alveolus with the tongue or any foreign body, to avoid hot and hard food, and not to bite on the side of the procedure. The patient should be advised to apply pressure for 20 min with a clean gauze pad in case of bleeding and contact the dentist if hemostasis does not occur:31,39

Conclusions

Patients who have suffered a heart attack often require dental treatment. Inflammation of the oral cavity not only reduces the quality of life, but can also contribute to deterioration of the course of ischemic heart disease. In most cases, dental treatment can be undertaken 6 weeks after myocardial infarction. It is important to eliminate pain, so local anesthesia with a vasodilator in a dose not exceeding 0.04 mg should be used. Antibiotic prophylaxis is usually not required. Visits should be short and carried out in the early afternoon. The patient should be in a comfortable sitting position. If the patient complains of retrosternal pain, the procedure should be discontinued and oxygen and nitrates administered. If there is no improvement, a re-infarction should be suspected and an ambulance should be called immediately. In the vast majority of cases, antiplatelet drugs and anticoagulants should not be discontinued prior to planned surgery, since there is a significantly higher risk of thromboembolism than of increased bleeding in these patients. In case of any doubts as to the patient's health and the possibility of dental treatment, the patient should be referred to a specialist to establish an individualized treatment plan.
