Background. Bisphosphonates (BPs) are widely used as anti-bone-resorptive agents. Despite the great benefits of BPs, they may cause local and systemic adverse side effects.

Objectives. The aim of this study was to evaluate the histopathological effect zoledronic acid (ZA), which belongs to BPs, has on the intrinsic tongue muscles in a rat model.

Material and methods. A total of 30 adult male albino rats were divided into 3 groups (10 rats each): group I served as a control; group II was given an intraperitoneal (i.p.) injection of 0.2 mg/kg of ZA once per week for 3 weeks; and group III received the same dosage of ZA, but for 8 weeks. After the animals were euthanized, the tongue tissue was dissected and examined histologically, histochemically and immunohistochemically.

Results. Histologically, a normal architecture of the muscle fascicles was observed in the control group. Group II showed degenerated muscle fibers with an indistinct sarcolemma. In group III, the muscle fibers were degenerated with severe sarcoplasmic dissolution. The histochemical examination using Masson's trichrome (MT) demonstrated a significant increase in collagen fibers in groups II and III as compared to the control group. The immunohistochemical results revealed a statistically significantly higher expression of nuclear factor kappa B (NF-κB) in the ZA-treated groups (II and III) as compared to the control group, with the highest mean value recorded in group III.

Conclusions. Zoledronic acid induced histopathological changes to the intrinsic tongue muscles, and this effect was exaggerated with a longer duration of administration.

Introduction

Bisphosphonates (BPs) are a class of drugs that are widely used in the treatment of osteoclast-mediated bone loss. They are synthetic, stable analogs of inorganic pyrophosphates – naturally occurring polyphosphates found in urine and blood serum. The ability of BPs to bind divalent cations such as Ca²⁺ helps them bind to bone mineral surfaces, predominantly at sites of active bone remodeling. Bisphosphonates are usually classified into 2 main groups with different mechanisms of action: non-nitrogen-containing bisphosphonates (non-N-BPs) and nitrogen-containing bisphosphonates (N-BPs). Of all the anti-bone-resorptive BPs available nowadays, those containing nitrogen in the heterocyclic ring (zoledronic acid – ZA) are 10,000 times more potent than non-N-BPs.

Zoledronic acid is well-established as a therapy for reducing skeletal-related events associated with bone metastases in several types of cancer, including prostate cancer. Moreover, ZA has been shown to improve immune surveillance against tumors, opening up new possibilities for therapeutic applications. However, several adverse effects have been demonstrated to be associated with ZA treatment. Bisphosphonate-associated osteonecrosis of the jaw and altered oral mucosal epithelium leading to delayed soft tissue healing are among the most significant side effects. An antiangiogenic effect of ZA has also been reported in many studies. It was observed that ZA could interfere with endothelial progenitor cell differentiation, impair endothelial cell proliferation, induce endothelial cell apoptosis, and modulate their adhesion and migration.

With this background in mind, the present study was performed to evaluate the possible effect of ZA treatment on the intrinsic tongue muscles in male albino rats using histological, histochemical and immunohistochemical analysis.

Material and methods

Ethical statement

This experimental study was carried out in the animal house of the Faculty of Medicine at Cairo University in Egypt, according to the recommendations and approval of the Institutional Animal Care and Use Committee of Cairo University (CU-IACUC) (approval No. CU/III/F/37/19).

Experimental design

A total of 30 adult male albino Wistar rats weighing 200 ±10 g were included in the study. All animals were housed in a sterile environment, maintained at room temperature (21 ±2°C) and 50–55% humidity with a 12-hour light cycle. The animals were fed with pelleted rat food and water ad libitum. The rats were randomly divided into 3 equal groups, with 10 rats in each group. The control group (group I) rats were given an intraperitoneal (i.p.) injection of saline solution. The group II rats received 0.2 mg/kg of ZA (Zometa®; Novartis, Basel, Switzerland) i.p. once per week for 3 weeks. The rats in group III received 0.2 mg/kg of ZA i.p. once per week for 8 weeks. All animals were euthanized by an i.p. injection of anesthetic overdose and the tongue was dissected.

Light microscopic examination

All tongue specimens were fixed in 10% formaldehyde solution. After staying in a fixative material for 24 h, the samples were washed under running water, dehydrated in an ethanol series, then cleared in xylene, and embedded in liquid paraffin. The tissues were then cut into 4–6-micrometer-thick sections and subjected to examination.

Histopathological examination

The sections were stained with hematoxylin and eosin (H&E).

Histochemical examination

The sections were stained with Masson’s trichrome (MT) for the detection of collagen fibers.

Immunohistochemical examination

The sections were stained with Masson’s trichrome (MT) for the detection of collagen fibers. The sections were deparaffinized and hydrated, then washed in 0.1 M phosphate buffer saline (PBS). Endogenous peroxidases were blocked by treatment with H₂O₂ in methanol. Non-specific background staining was inhibited through incubation at room temperature for 30 min in 0.3% bovine serum albumin. The sections were incubated with primary antibodies for nuclear factor kappa B (NF-κB) at room temperature for 60 min. Then, the sections were washed in buffer 3 times, each time for 5 min, and incubated for further 30 min with biotinylated secondary antibodies, followed by washing. Diaminobenzidine solution was used as a chromogen and Mayer’s hematoxylin was used as a counterstain for 5 min. Phosphate buffer saline was used as a negative controller. The slides were then finally mounted. Positive immunoreactivity for NF-κB appeared in the form of brown coloration of the cytoplasm and/or nuclei of the immunoreactive cells.

Image analysis

For the evaluation of staining affinity, the area percentage of collagen fibers in the sections stained with MT as well as NF-κB immunoreactivity were measured.
by an image analyzer (Leica DM LB2 with QWin Plus image analysis software; Leica Camera, Wetzlar, Germany). The image analysis was done in different, non-overlapping fields of each specimen.

**Statistical analysis**

The data obtained from the image analysis was statistically described in terms of mean ± standard deviation (M ±SD). Student’s t-test was used for multiple pairwise comparisons. A probability value (p-value) of <0.05 was considered statistically significant. All statistical calculations were done using Microsoft Excel 2007 (Microsoft Corporation, Redmond, USA) and SPSS for Windows v. 15 (SPSS Inc., Chicago, USA).

**Results**

**Histopathological results**

Group I (the control group) showed a normal architecture of the muscle fascicles. The muscle fibers were arranged differently, with some being cut longitudinally while others were cut transversely. The fibers demonstrated homogenous acidophilic sarcoplasm with multiple peripheral elongated nuclei beneath a well-defined sarcolemma (Fig. 1A).

The muscle fascicles in group II were ill-defined as compared to the control group. Degenerated muscle fibers with an indistinct sarcolemma were also detected. Degeneration was in the form of serration, widely distributed sarcoplasmic dissolution and nuclear atypia (change in size and position). Chronic inflammatory cellular infiltration was obvious (Fig. 1B).

Group III demonstrated the degeneration of most of the intrinsic muscle fibers of the tongue. Degenerated muscle fibers appeared swollen with severe sarcoplasmic dissolution. The remnants of eosinophilic muscle fibers were also observed within the coalesced fascicles. A thickened perimysium with marked inflammatory cell infiltration was noticed. Histiocytes appeared with different patterns: with homogenous basophilic cytoplasm, with a central basophilic body, or with a regular pattern of giant, deeply basophilic stained cells. The accumulation of fat droplets was also noted (Fig. 1C).

**Histochemical results**

The histochemical examination using MT for the detection of collagen fiber bundles (the stains in blue) revealed that the tongue intrinsic muscles of the control group consisted of tightly packed, regularly arranged, parallel perimysial collagen bundles (Fig. 2A). The mean collagen area percentage was 7.06 ±0.21.

Disorganized perimysial collagen fiber bundles were observed in group II. Some areas showed dense, wavy collagen bundles related to clumped muscle fascicles. However, other areas had a thin perimysium (Fig. 2B). The mean value of collagen area percentage was 17.77 ±2.19; statistical analysis revealed that it was significantly higher than that of group I (p = 0.015).

Group III exhibited dense, curly, disorganized perimysial collagen bundles (Fig. 2C). The highest mean value of collagen area percentage was found in this group – 23.55 ±1.11. Statistical analysis revealed that this mean value was statistically significantly higher as compared to group I (p = 0.004), but it was not statistically significantly different from that of group II (p = 0.081).

![Fig. 1. Photomicrograph of the intrinsic tongue muscles (hematoxylin and eosin (H&E) staining)](image-url)
High cytoplasmic and nuclear immunoreactivity for activated NF-κB was noted in group III (Fig. 3C). The highest mean percentage of the area of NF-κB immunoreexpression was revealed in this group – 36.32 ±2.56. Statistical analysis revealed that this value was statistically significantly different from that of both group I \( (p = 0.000) \) and group II \( (p = 0.003) \).

**Discussion**

Zoledronic acid is a highly effective drug that inhibits osteoclast-mediated bone resorption.\(^{13}\) Although ZA is well-tolerated, numerous short-term and long-term adverse reactions have been reported to be associated with...
the administration of ZA. Severe musculoskeletal pain is one of the side effects related to BP treatment. It has been reported to occur days or months (median time: 14 days) after starting a BP therapy and to resolve only if the therapy is stopped. Based on this clinical observation, the skeletal muscle was the tissue of choice to be investigated in the current study.

The tongue is a unique skeletal muscle with differences in the muscle fiber composition when compared with limb, masticatory and orofacial muscles, most likely reflecting genotypic and phenotypic functional specialization in oral function. The prevalence of type II fibers, regional differences in the fiber composition and complex muscle structure generally suggest rapid and flexible actions in shaping and positioning the tongue while performing vital functions, such as speech, swallowing, mastication, and breathing. These facts reinforce the decision to select the intrinsic tongue muscles to be the examined tissue in this study.

The histopathological examination in the present study revealed a normal architecture of the muscle fascicles in the control group. On the other hand, group II (3 weeks of ZA treatment) showed degenerated muscle fibers with an indistinct sarcolemma. Swollen muscle fibers with severe sarcoplasmic dissolution were observed after 8 weeks of ZA administration (group III). Inflammatory cellular infiltration was noticed in both ZA-treated groups. Interestingly, the muscle tissue in the group III rats was infiltrated by various patterns of histiocytes. Cells with central basophilic bodies was one of the patterns observed in the present study. Histologically, as explained by Gillett et al., this pattern is a result of defective phagolysosomal activity within macrophages; thus, it will contain partially digested bacteria. This leads to the deposition of calcium and iron, resulting in a basophilic inclusion structure (Michaelis–Gutmann bodies). Large macrophages which are present at sites of infection (von Hansemann cells) exhibit numerous secondary lysosomes containing partially digested organisms. The fusion and calcification of these lysosomes result in the formation of intracytoplasmic bodies called Michaelis–Gutmann bodies. It has been proposed that local bacterial antigen load, due to tissue necrosis, might lead to the accumulation of macrophages, which would facilitate the local production of Michaelis–Gutmann bodies. Such an explanation could be supported by the current study, suggesting extensive muscle degeneration in group III. Another postulate could be that bacterial invasion may occur as a result of the negative effect of BPs on the adhesion and metabolism of oral mucosal cells.

The degeneration and inflammatory cellular infiltration associated with ZA treatment observed in this study supports previous studies, which reported obvious histopathological changes following ZA administration. These changes included severe tubular degeneration, hypereosinophilia, cell necrosis, and interstitial fibrosis in the renal tissue. Furthermore, necrotic zones and intense acute inflammatory infiltrate were observed in the alveolar bone tissue of rats receiving ZA.

The NF-κB complex is activated in response to a variety of stimuli, including bacterial infection, exposure to proinflammatory cytokines and growth factors, and oxidative and biomechanical stress. In this study, activated NF-κB was immunohistochemically located in the tongue muscle tissue as an indicator of an inflammatory response and oxidative stress. The results showed that NF-κB immunoreactivity was higher following ZA administration, with the greatest mean value recorded after 8 weeks (group III). This was in accordance with Muratsu et al., who revealed that ZA activated NF-κB expression in a cultured murine macrophage cell line.

The correlation between the histopathological and immunohistochemical results observed in the present study could be explained by understanding the ZA molecular mechanism of action. Zoledronic acid has been reported to be the most potent N-BP in inhibiting the enzymes farnesyl diphosphate synthase (FPPS) and geranylgeranyl diphosphate synthase (GGPPS) in the mevalonate pathway.

The inhibition of FPPS has been suggested to increase the intracellular levels of isopentyl pyrophosphate, which induces T-cell activation; this results in the release of inflammatory cytokines. It has also been reported that the inactivation of GGPPS results in the stimulation of the proinflammatory mitogen-activated protein kinases and NF-κB signaling pathways. Although NF-κB regulates the expression of proinflammatory cytokines, these cytokines are considered potent activators of NF-κB. This establishes a positive feedback loop, resulting in the overstimulation of NF-κB. It has been suggested that the persistent stimulation of the skeletal muscle fibers through positive feedback loops may result in the overstimulation of NF-κB. This hypothesis could explain the enhanced NF-κB immunoreactivity observed in the present study. Nuclear factor kappa B has been reported to be one of the most important signaling pathways related to the loss of the skeletal muscle mass. The activation of NF-κB in the skeletal muscle leads to the degradation of specific muscle proteins, induces inflammation and fibrosis, and blocks the regeneration of myofibers after injury/atrophy.

The MT staining procedure was used in the present study to assess the extent of fibrosis in the intrinsic tongue muscles. A progressive increase in the amount of collagen fibers was observed among the experimental groups. The lowest mean value was recorded in the control group, whereas the highest value was recorded in group III. An increase in fibrosis was concomitant with a degree of muscle injury.

According to Lańcut et al., an increase in the intrafascicular connective tissue usually represents a response to myofiber loss, wherein fibroblasts replace the damaged area, with the subsequent formation of collagen fibers.
It has also been suggested that a persistent inflammatory response alters the extracellular environment and increases the secretion of various inflammatory cytokines, which contributes to muscle fibrosis.  

Conclusions

It can be concluded that ZA induces histopathological changes in the intrinsic tongue muscles, and that this effect is exaggerated by a longer administration. These changes might predict a poorer functional outcome of these muscles.

Recommendations

Since the intrinsic tongue muscles contribute substantially to chewing, swallowing, speaking, and respiration, it is recommended that clinicians be aware of the expected poor outcomes in these functions in patients under ZA treatment. Further studies need to be performed on other muscles of the aerodigestive tract involved in swallowing and mastication, as well as on females, using various investigatory tools.
