Abstract

\textbf{Background.} Heat shock protein 27 (HSP-27) is a member of the small-molecular-weight HSP family, the expression of which is increased when cells are exposed to elevated temperatures or any other kinds of stress; it seems that the cellular protective properties this protein demonstrates might also help cancer cells stay immortal. Family members of HSPs are either expressed continuously or controlled inductively, and are present in different subcellular structures.

\textbf{Objectives.} The aim of this study was to investigate the prognostic value of HSP-27 expression in the histological grades of oral squamous cell carcinoma (OSCC).

\textbf{Material and methods.} In the present study, HSP-27 expression was compared immunohistochemically among 30 cases with OSCC (15 men and 15 women), ranging between 22 and 74 years of age (mean age: 48 years). The cases were divided into 3 groups ($n = 10$) according to the histological grade.

\textbf{Results.} While all grades expressed HSP-27 in the cancerous epithelial cells, the intensity of expression rose gradually from grade 1 to grade 3 tumors (grade 1 < grade 2 < grade 3). The statistical analysis indicated significant differences between the 3 groups ($p = 0.000$).

\textbf{Conclusions.} This study has found that HSP-27 may be used as a marker for the histological grades of OSCC and that its expression may be an indicator of the biological behavior of the tumor.

\textbf{Key words:} squamous cell carcinoma, heat shock proteins, overexpression

Introduction

Heat shock proteins (HSPs) are conserved molecular chaperones; they are ubiquitous and have several functions in cellular homeostasis, including the regulation of gene expression, the replication of DNA, the transduction of signals, differentiation, apoptosis, and cellular survival or immortalization. They also protect cells from various kinds of stress, such as hypoxia, ischemia or rapid increases in temperature.1

Mammalian HSPs have been arranged into 6 families depending on their molecular size: HSP100, HSP90, HSP70, HSP60, HSP40, and small HSPs (15–30 kDa), including heat shock protein 27 (HSP-27). Family members of HSPs are either expressed continuously or controlled inductively, and they are present in different subcellular structures.2

Heat shock protein 27 belongs to the family of small HSPs, which play essential roles in cells under physiological conditions and prevent cells from damage caused by stress. It is a molecular chaperone helping cells remain stable under various stress conditions, such as heat shock, irradiation, oxidative stress, endoplasmic reticulum (ER) stress, and chemotherapy for cancer patients.3

Head and neck cancer is one of the most critical malignancies in the world; it is the 3rd most common cancer in developing countries,4,5 and squamous cell carcinoma has the highest mortality rate among head and neck cancers (54%). Therefore, a huge number of studies have been done on this neoplasia so far,6,7 with many advances being made in the field of cancer treatment. However, little improvement has been achieved.4,5

Tumor grading is related to how similar the cancer tissue is to the parent tissue, and to the ability of the dysplastic squamous epithelial cells to produce keratin. The biological behavior of the tumor relates to its histopathological grading.8 Additionally, several proteins are called markers and can predict the biological behavior of the tumor. Many studies have been done to assess these markers and their ability to initiate carcinogenesis.7

The aim of the present study was to investigate the prognostic value of HSP-27 expression in the histological grades of oral squamous cell carcinoma (OSCC).

Material and methods

Approval to conduct the study was granted by the Ethics Committee at the University of Damascus in Syria (approval ref.: 1806/2018).

The sample population consisted of 10 formalin-fixed, paraffin-embedded blocks of squamous cell carcinoma in each grade (grades 1–3; a total of 15 men and 15 women at the age of 22–74 years and 10 blocks of normal epithelium (biopsies taken from the mucosa that covers the bone before implantation – the para-keratinized mucosa).

Sections were cut from the blocks, and used for both histological and immunohistochemical examination. Four sections were made and loaded onto slides. The sections were deparaffinized, washed in deionized water and subjected to antigen retrieval. A solution of approx. 3% hydrogen peroxide was used to block endogenous peroxidase.

The standard streptavidin–biotin–peroxidase complex method was performed to bind the primary antibodies. The reaction products were visualized by treating them with 3,3’-diaminobenzidine (DAB) (Bio SB, Inc., Santa Barbara, USA) solution diluted according to the manufacturer’s instructions. The manufacturer’s data: Twenty micrometers of DAB chromogen were added to each 1 mL of poly-detector DAB buffer. For the control samples, the serial sections were treated with all the previous reagents, but without the primary antibody; the samples were confirmed to be unstained.

Heat shock protein 27 was assessed by counting the stained cells in 4 non-overlapping microscopic fields (positive cells showed positivity for the antibody as brown color in the cytoplasm) and by assigning it a score for color intensity (0 – no staining; 1 – mild and pale staining; 2 – moderate staining; and 3 – intense staining).

The Kruskal–Wallis and Mann–Whitney tests were used in the statistical analysis. The χ² test was conducted to determine whether there was a statistically significant difference between the groups: the χ² number was 16.057 with a p-value of 0.000 (much smaller than 0.05). These results refer to the presence of a significant difference between the groups.

Results

– Normal epithelium (n = 10):

The supra-basal layers of normal epithelium expressed moderately positive staining in almost all 10 samples (Fig. 1).

– OSCC grade 1 (n = 10):

All cancerous cells showed positive expression for HSP-27 in all 10 samples; the staining was mild and pale (Fig. 2).

– OSCC grade 2 (n = 10):

All cancerous cells showed positive expression for HSP-27 and the samples were moderately stained with the HSP-27 antibody (Fig. 3).

– OSCC grade 3 (n = 10):

All cancerous cells showed positive expression for HSP-27, with intense staining in almost all of the samples (Fig. 4).
Head and neck squamous cell carcinoma (HNSCC) is considered the 6th most prevalent cancer in the world. Radiotherapy has been the primary treatment for patients affected with this inoperable disease.

In spite of these huge improvements, the lowest 5-year survival rate associated with HNSCC has remained the same, due to frequent recurrence after the initial therapy. Therefore, advanced therapeutic methods should be applied to defeat resistance to anticancer therapy. One option suggests suppressing specific physiological proteins with antiapoptotic roles, such as HSP-27. The overexpression of this protein has been detected in many cancers, including breast cancer, prostate cancer, and gastric cancer.

Heat shock protein 27 has also been found to be overexpressed in HNSCC cases. In addition, HSP-27 has been associated with the most serious behaviors of cancer cells - metastasis, short survival time and poorly differentiated cells. With its antiapoptotic property, HSP-27

Discussion

Head and neck squamous cell carcinoma (HNSCC) is considered the 6th most prevalent cancer in the world. Radiotherapy has been the primary treatment for patients affected with this inoperable disease.
causes the resistance of cancer cells to chemoradiotherapy. Heat shock protein 27 plays a protective role for tumor cells against oxidative pressure with the unique ability of glucose-6-phosphate-dehydrogenase to keep glutathione in its decreased form, and also with the activity of an in vivo chaperone against oxidized proteins. Therefore, decreasing the antioxidant protection of tumor cells through HSP-27 suppression should augment the benefit of the cytotoxic competence of radiotherapy and enhance the clinical outcome.

Apart from that, HSP-27 participates in the regulation of Akt (serine/threonine kinase), which is an important indicator molecule for cell survival. Heat shock protein 27 plays an essential role in the chemoresistance of the squamous cell carcinoma of the tongue (SCCT) cells via its extracellular and intracellular signaling process. Heat shock protein 27 could serve as a useful biomarker and a precise therapeutic target in the treatment of SCCT.

There has been a particular increase in the amount of HSP-27 in multidrug-resistant SCCT cells. Both HSP-27 knockdown and anti-HSP-27 antibody treatment oppose chemoresistance. Inversely, the overexpression of HSP-27 and recombinant human HSP-27 treatment increase chemoresistance.

Furthermore, chemotherapy has been reported to have a significant effect on the HSP-27 levels by inducing the protein in SCCT cells and their culture medium as well as in the tumor tissues and serum of SCCT patients. For that, the overexpression of HSP-27 can predict the poor outcome of SCCT patients receiving chemotherapy. Specitically, extracellular HSP-27 binding with toll-like receptor 5 (TLR5) and the activation of nuclear factor kappa B (NF-kB) signaling keep cancer cells alive. Toll-like receptor 5 knockdown or the level of the restored inhibitor of NF-kB (IκBα) damage extracellular HSP-27-induced NF-kB transactivation and chemoresistance. Additionally, the action of intracellular HSP-27 binding to BAX and BIM prevents their translocation to the mitochondria, and cytochrome C is subsequently released under chemotherapy, which causes the suppression of the mitochondrial apoptotic pathway.

Moreover, some studies have reported the overexpression of HSP-27 in cancer stem cells. One group of researchers showed the augmented expression and phosphorylation of the protein in breast cancer stem cells. They revealed that HSP-27 had to play a role in the epithelial–mesenchymal transition process to help with the maintenance of cancer stem cells. Another study illustrated that lung cancer stem cells had elevated levels of the activated type of HSP-27 due to superoxide and traditional chemotherapy treatment.

The expression of HSP-27 in well-differentiated OSCCs was significantly lower than in moderately differentiated OSCCs ($p = 0.000$). The analysis showed a clear correlation between the expression of HSP-27 and the histopathological grade of OSCC ($p = 0.000$) (Table 1, Fig. 5). We attribute this to the major role of the protein as an anti-apoptosis agent helping cancerous cells remain immortal.

These findings are in agreement with previous studies, e.g., by Lambot et al., who investigated HSP-27 expression in esophagitis, esophagus dysplasia, and the 3 grades of esophagus squamous cell carcinoma in comparison with the normal epithelium of the esophagus. The study concluded that there was a clear relationship between high HSP-27 expression and the atypia of cells. Also, a study by Mese et al., which was conducted on biopsies from both OSCC areas and metastasis areas in different parts of the body, reported results similar to ours, with a stronger expression of the protein for metastasis biopsies. Muzio et al. conducted research with exactly opposite results. The correlation was between low-grade OSCC and the intensity of HSP-27 expression. We relate this to the variation of standards in the 2 studies, as they used biopsies taken from patients who had already gone through multiple types of treatment whereas our samples were taken and studied before any treatment.

**Conclusions**

This study has found that HSP-27 can be used as a marker for the histological grades of OSCC and that its expression is a possible indicator of the biological behavior of the tumor.
