Abstract

Osteopetrosis is a rare hereditary bone disorder that results in an increase in bone density due to gene mutations and osteoclastic dysfunction. This may lead to cranial nerve compression, bone fractures and osteomyelitis. Osteomyelitis of the maxilla is rare even in osteopetrosis patients.

We report on a case of a 25-year-old male who presented with multiple episodes of osteomyelitis of the maxilla following dental extractions. The patient was initially managed with the incision and drainage of an acute infection, and intravenous amoxicillin-clavulanic acid. This was followed by the debridement of necrotic bony margins and packing with bismuth iodoform paraffin paste (BIPP) as well as long-term clindamycin. Once osteomyelitis was clear, the primary closure was achieved with a buccal advancement flap and supported by an acrylic obturator. Challenges in the management are highlighted, including preparing for a surgical intervention a patient with chronic low hemoglobin levels and a lack of healthy bony margins in the maxilla. The literature is also reviewed for similar cases.

Key words: osteomyelitis, maxilla, osteopetrosis

Introduction

Osteopetrosis is a rare hereditary bone disorder that results in an increase in bone density due to gene mutations and osteoclastic dysfunction. The disorder is classically divided into 3 types with variable clinical features. The dominant form of osteopetrosis is typically seen in adults with a late onset whereas the 2 recessive forms of osteopetrosis are typically observed in children with an early onset and a high mortality rate. As bone expansion occurs, marrow spaces become obliterated, which results in fractures, poor wound healing and an increased risk of infections, such as osteomyelitis. Osteomyelitis of the maxilla is relatively rare owing to rich collateral blood supply and thin cortical bone. The diagnosis is established with a thorough history, and physical and radiographic examinations, with the latter being the mainstay. Treatment principles involve managing the identified complications. In the case of osteomyelitis, conservative and preventative care principles play a significant role in the management of patients with osteopetrosis. It is vital that patients with osteopetrosis are made aware of good oral hygiene and dental care practices so as to avoid the need for further treatment. Carious teeth should thus initially be treated with restorations or the endodontic therapy with the aim of preventing tooth extractions and the subsequent surgical complications, such as osteomyelitis. If conservative and preventative measures are compromised, and patients with osteopetrosis develop osteomyelitis, the debridement of necrotic tissue with an adjunctive antibiotic therapy is mandated.1

Case report

A 25-year-old male patient was referred to the Department of Maxillofacial and Oral Surgery at the University of the Western Cape, Tygerberg Hospital in Cape Town, South Africa, with chronic infections and recurrent swelling. The patient reported that the infective process had started 6 months ago, after the extraction of the upper right molar, and had exacerbated 1 day prior to presentation at the clinic.

Past medical history revealed that the patient sustained multiple bone fractures throughout his life, such as forearm and ankle fractures. Upon proceeding with a detailed history, and physical and radiographic examinations, the diagnosis of osteopetrosis with underlying osteomyelitis was confirmed. The patient was not on any chronic medications and had not been on antiresorptive/antiangiogenic agents previously.

Clinically, the patient presented with soft, tender, right facial swelling associated with the right canine space region and the upper lip. Intraorally, the mandible appeared edentulous and pus discharge was found in the right maxillary region with a draining fistula associated with the right first molar area (Fig. 1). A radiographic examination demonstrated increased bone opacity, poorly pneumatized paranasal sinuses and multiple unerupted teeth (Fig. 2). Additionally, cone-beam computed tomography (CBCT) further illustrated increased bone opacity with poor differentiation between medullary and cortical bone (Fig. 3).
With regard to the management of the patient at this point, the retained root of a maxillary first molar was surgically removed, incision and drainage were performed, a pus swab was taken, and augmentin IV was administered for 7 days. Following this initial intervention, swelling decreased and the patient reported the alleviation of pain.

Three weeks following discharge, the patient returned, complaining of severe pain and tenderness associated with the same area. An intraoral examination revealed pus discharge from a non-healing maxillary first molar socket with areas of exposed bone. The region was then debridged and packed with bismuth iodoform paraffin paste (BIPP) gauze, the canine space was explored and irrigated, and biopsy was performed. Thereafter, the patient was admitted for 7 days for monitoring and irrigation, with an adjunctive antibiotic therapy in the form of 1.2 g of augmentin, administered intravenously (i.v.) every 8 h pending microscopy, culture and sensitivity testing. At day 3 of admission, the patient was switched to 600 mg of clindamycin i.v. every 6 h, as the cultured bacteria were resistant to penicillin. Hematological studies revealed reductions in the red blood cell count (2.78 × 10^{12} /L), hemoglobin (6.8 g/dL) and platelet count (146 × 10^9 /L) with the C-reactive protein level markedly elevated (83 mg/L). Additionally, the iron level was at the lower limit of the normal range, requiring the prescription of ferric sulfate. The histological examination of the obtained biopsy showed strips of acanthotic, stratified squamous oral mucosa with dense submucosal chronic inflammation (Fig. 4). Fragments of non-vital bone with the surrounding cellular debris, hemorrhage and basophilic bacterial colonization were noted, which was indicative of a sequestrum.

Following that, the patient required 2 additional debridements under general anesthesia with blood transfusions due to chronic low hemoglobin. The patient was also prescribed pentoxifylline and tocopherol orally to aid bone healing. The wound was then closed, primarily with a buccal advancement flap, and an acrylic obturator was used to support the wound.

**Discussion**

Multiple genetic mutations are responsible for the presentation of osteopetrosis. The mutated genes of significance include CLCN7 and TGIRG1, which results in the functional defects of the enzyme carbonic anhydrase II. Osteoclasts ultimately cannot form ruffled borders, causing defective bone resorption with the subsequent accumulation of bone, thereby increasing bone density and the fracture risk.

Osteopetrosis is classified into 3 clinical categories, namely benign autosomal dominant, severe malignant autosomal recessive and intermediate mild autosomal recessive. The dominant form of the disorder is more common in adults. In contrast, the rarer autosomal recessive types are typically associated with an early onset and poor prognosis.

Bones in patients with osteopetrosis are poorly vascularized. This adversely affects the healing process and results in a marked increase in infection susceptibility. As bone becomes denser, its marrow cavities and the pulpal chambers of the teeth become obliterated with the resultant constriction of the neurovascular bundles supplying the jaws and the teeth. The extension of bone into the cranial nerve foramina and marrow cavities may compromise both hematologic and neurological functions. Hematological complications include frequent infections, profound anemia and hepatosplenomegaly, as in the case of our patient. Neurological complications may result in nerve palsies, deafness and blindness. Additionally, dental caries and bone necrosis may also develop as a consequence of bone expansion, which ultimately results in osteomyelitis. Osteomyelitis is thus a well-known complication associated with osteopetrosis due to its hypovascular nature. This infection commonly presents in the mandible post-extraction or after the surgical exposure of bone, warranting adequate infection control practices before and after dental surgical procedures.

In the dental setting, patients with osteopetrosis present with complications such as dental caries, premature tooth loss, delayed eruption of teeth, enamel hypoplasia, tooth crown and root malformations, and thickened lamina dura.

The diagnosis of osteopetrosis is based on both clinical and radiographic findings, with the latter being the mainstay. A radiographic examination reveals diffuse osteosclerosis, involving the spine, the skull, the pelvis, and appendicular bones. Additionally, cortical thickening with the resultant medullary encroachment can be visualised. Differential diagnoses that are to be considered include metaphyseal dysplasia, pyknodystostosis, diaphyseal sclerosis, osteopathia striata, osteopoikilosis, melorheostosis, Camurati–Engelmann disease, and infantile cortical sclerosis.

  - cefazolin for 7 days  
  surgical management:  
  - sequestrectomy |
| Arunkumar et al. 2011        | 54            | male             | chronic discharge, swelling and an ulcer over the left cheek, a discharging sinus tract inferior to the left outer canthus, oroantral fistula | destruction of the alveolar process in the 2nd quadrant and the left zygomatic arch | - ofloxacin  
  - extractions of involved teeth  
  - excision of the fistula  
  - sequestrectomy |
| Balan et al. 2011            | 8             | male             | painful left-sided facial swelling with purulent discharge from a carious primary molar | increased bone density, diffuse sclerosis, multiple unerupted teeth               | - systemic antibiotics  
  - local debridement of the maxilla |
| Khademi et al. 2011          | 15            | male             | bilateral facial pain and swelling with infraorbital sinuses tract drainage, vision and hearing problems | obliteration of the maxillary sinuses, sequestration of the maxilla and the zygomatic bone | initial management:  
  - clindamycin  
  surgical management:  
  - curettage  
  - sequestrectomy  
  - sinus tract excision |
| Ambika et al. 2010           | 28            | male             | non-healing extraction socket with exposed necrotic bone in the right molar region associated with painful, extraorally draining facial swelling | increased bone density, erosion of the buccal cortices of the right maxilla, the zygomatic bone, the lateral orbital wall, and the maxillary sinus | initial management:  
  - ciprofloxacin  
  - local debridement  
  - sequestrectomy  
  Partial maxillectomy was planned, but the patient refused treatment. |
| Oğütcen-Toller et al. 2010    | 18            | female           | purulent discharge from the infraorbital and left maxillary molar regions, partial edentulism with multiple malformed teeth, blindness | diffuse hyperdensity of the maxilla and the mandible, sequestration formation, multiple impacted teeth | initial management:  
  - amoxicillin for 7 days  
  surgical management:  
  - extractions of all partially impacted and malformed teeth  
  - sequestrectomy  
  post-operative antibiotics:  
  - sultamicillin and ornidazole for 5 weeks  
  - treatment was altered to clindamycin for 1 week, sultamicillin and ornidazole for 3 weeks followed by cefuroxime axetil for 4 weeks |

CT – computed tomography.
If patients start exhibiting such symptoms as fractures, sepsis, or hematological or neurological abnormalities, medical consultation and management may be necessary. Management principles aim to modulate and stimulate osteoclastic activity. Attempts at stimulating osteoclastic activity have been made previously, all with variable success rates, such as utilizing the calcitirol therapy, the regulation of calcium, steroids, and parathyroid hormone. Palliative treatment involves the debridement of grossly necrotic bone and nerve decompression.

Hemopoietic stem cell transplantation has been proven to be a useful modality to improve the survival rate of patients with the autosomal recessive variants of osteopetrosis.

Treatment modalities that are utilized for osteomyelitis in the jaws secondary to osteopetrosis include incision and drainage, dental extractions, an antibiotic therapy, sequestrectomy, saucerization, decortication, jaw resections, and hyperbaric oxygen. Obturators are ideally used to close defects; free bone grafts are not recommended due to the compromised blood supply to the graft bed.

No definitive treatment protocol currently exists for osteopetrosis, as shown in Table 1.

In conclusion, from our experience in the management of this patient and the reviewed literature, patients with osteopetrosis complicated by osteomyelitis of the maxilla should be treated with a long-term antibiotic therapy (amoxicillin/clavulanic acid and/or clindamycin), accompanied with the surgical debridement/sequestrectomy and packing the site with a medicament (BIPP or Whitehead's varnish) to aid in healing and to prevent further infections. Regular long-term follow-up is vital to assess healing and to prevent the dissemination of the disease process.
